Abstract: The delayed retirement credit (DRC) increases monthly OASI (Old Age and Survivors Insurance) benefits for primary beneficiaries who claim after their full retirement age (FRA). For many years, the DRC was set at 3.0 percent per year (0.25 percent monthly). The 1983 amendments to Social Security more than doubled this actuarial adjustment to 8.0 percent per year. In this paper, we use administrative data from the Social Security Administration (SSA) to estimate the effect of this policy change on individual claiming behavior and labor supply. We focus on the first half of the DRC increase (from 3.0 to 5.5 percent) given changes in other SSA policies that coincided with the later increases. Our findings demonstrate that the increase in the DRC led to an increase in delayed claiming of social security benefits and strongly suggest that the effects were larger for those with higher lifetime incomes, who would have a greater financial incentive to delay given their longer life expectancies. Furthermore, liquidity constraints play an important role in responsiveness to DRC increases. We do not find evidence of changes to labor supply.

Keywords: Social security, claiming behavior, retirement

I. INTRODUCTION

Old Age, Survivors, and Disability Insurance (OASDI) – also known as Social Security - is the largest social insurance program in the United States. This program paid an average monthly benefit of \$1,422 to 64.9 million Americans in 2020, with total OASDI expenditures in 2020 amounting to \$1.11 trillion.¹ By far the largest group of OASDI recipients is retired workers, accounting for 46.3 million program beneficiaries with an additional 3.0 million dependents of this group in this same year. An individual with at least 10 years of earnings² can claim retired worker benefits as early as the month in which the individual turns 62, with an actuarial adjustment for each month of delaying claiming beyond that point.

Social Security represents a substantial source of income for retired workers and is the primary source of income for most individuals aged 65 and over. However, the trust fund is predicted to deplete its reserves by 2035 (Annual Trustees Report, 2020).³ Understanding how individuals choose to claim benefits and respond to program rules is essential for implementing policies to address significant concerns surrounding the long-term solvency of this program. However, despite the substantial body of literature examining different aspects of Social Security, little attention has been paid to a key component of retirees' benefit calculation: the Delayed Retirement Credit (DRC). The DRC directly increases the financial incentive to claim retired worker benefits later through adjusting the monthly benefits upwards for those who delay claiming.

¹ 2021 Social Security Administration Annual Statistical Supplement, 4.A OASDI: Trust Funds, Table 4A.3; 5.A OASDI Current-Pay Benefits: Summary, Table 5.A1

² An individual needs to earn 40 quarters of credits, where credits are received for work in covered earnings. See <https://www.ssa.gov/benefits/retirement/planner/credits.html> for more information.

³ See <https://www.ssa.gov/oact/tr/2020/tr2020.pdf> for additional information. The Congressional Budget Office projects a depletion date 3 years earlier in 2032

In this paper, we present new evidence on how changes in the Delayed Retirement Credit affect the timing of decisions to claim Social Security retirement benefits and labor supply. The age that a person claims Social Security, together with the average indexed monthly earnings (AIME), determines the benefit amount that will be received. Those who claim after their full retirement age (FRA) have their monthly benefits scaled up by the DRC, while benefits are reduced for those who claim earlier than FRA. Under the 1983 amendments, the DRC rose from just 3.0 percent per year for those born prior to 1925 to 8.0 percent per year for those born in 1943 and later. This DRC increase was phased in gradually in 0.5 percentage point increments every two years, so that those born in 1925 and 1926 had a 3.5 percent annual DRC, those born in 1927 and 1928 had a 4.0 percent annual DRC, and so forth through the 1943 birth cohort. For this cohort and all subsequent ones, the DRC was equal to 8.0 percent.

We study the effects of these increases on individual claiming and working behavior through using Social Security administrative micro-data, with individual level records of claiming for eleven birth years spanning 1923 through 1933. We focus on the first five changes in the DRC since the latter five changes coincided with other changes to retired worker benefits including the increase in the full retirement age (FRA) and the elimination of the earnings test for earnings received after FRA. We leverage the highly detailed nature of this data set to empirically estimate the effect of DRC increases on the probability that individuals delay claiming beyond FRA.

We first present simulations of the expected present value of claiming at different ages and highlight two key relationships: increases in the DRC increase the financial incentives to claim later, and there is substantial heterogeneity in the propensity to claim later. In particular, we predict that those with higher lifetime incomes are more affected by DRC increases, given that they are expected to receive a larger monthly benefit for a longer period of time. This may constitute a form

of adverse selection. To the extent that those with the highest lifetime incomes (and longest life expectancies) respond to the policy change by delaying claiming, the present value of outlays by the Social Security program may be significantly larger as a result of the policy change.

We use Social Security administrative data from a 10 percent random sample of all beneficiaries and focus on individuals born between 1923 through 1933 to implement a regression discontinuity with a second difference (RD-DD) strategy to estimate the causal effects of DRC increases. The DRC is uniquely determined by the year of birth, which creates several cutoffs between those with birth months of December of year t and January of year $t+1$. We compare claiming decisions of individuals born around the end of the calendar year, to those of individuals born around the beginning of the next calendar year. The individuals in the two groups are likely similar in nature except that those born right after January of a new calendar year experience a higher DRC rate compared to those born right before January.

To account for the possibility that individuals born early in the calendar year claim differently than those born later in the previous calendar year for other reasons, we utilize an equal number of placebo birth windows. For example, there was no change in the DRC from year-of-birth 1925 to 1926 or from 1927 to 1928. However, there was an increase from 1926 to 1927. We are careful to construct our sample to account for simultaneous shifts in other Social Security program rules – namely the increases in the full retirement age (FRA, which began with the 1938 year-of-birth) and the earnings test (ET, which was passed in April 2000) – to isolate the effect of the DRC. Our main analysis focuses on the effects for men, due to large changes in the working and claiming behavior of women (and corresponding changes in the composition of women claiming retired worker benefits) during our period of interest.

We find consistent empirical evidence that men respond, albeit moderately, to increases in the DRC among the full sample of men born between 1923 through 1933. More specifically, a 0.5 percentage point increase in the DRC increases claiming at or beyond age 66 (12 months after FRA) by 0.25 percentage points. Furthermore, we find suggestive evidence of adverse selection, as the estimated effect for those in the top earnings decile is much larger in magnitude than the effect for those with earnings below the median. These differences are however only suggestive and are not statistically significant. We do show that changes in claiming behavior are driven by individuals less likely to be liquidity constrained, illustrating that frictions like liquidity constraints prevent delays in claiming. We further explore whether changes in the DRC also affected labor supply; while claiming need not coincide with retirement, changes to claiming behavior could affect the choice to work. We do not find evidence of DRC induced changes in the decision to work either before or after the FRA. This suggests that changes in the DRC were not large enough to substantially shift working behavior.

A substantial body of literature has explored retired worker claiming behavior, generally finding that individuals claim benefits sooner than what might be predicted through economic theory as optimal. While researchers have noted a variety of factors that contribute to early claiming behavior, there has been surprisingly little exploration of a whether a policy specifically aimed at promoting later claiming is effective. While we do show evidence of DRC induced changes to claiming behavior, we note that overall rates of delayed claiming are low. We discuss how other factors, such as knowledge of program rules, mitigate the effectiveness of DRC increases. This suggests that for the purposes of promoting large shifts in claiming of Social Security benefits, increases to the DRC alone might not be enough.

The outline of the paper is as follows. In Section 2, we provide details on Social Security's retired worker claiming rules along with background on the 1983 Social Security Amendments. We also briefly summarize the related previous literature. Section 3 describes our sources of administrative data from the Social Security Administration along with the construction of our analysis sample. We then provide an overview in Section 4 of OASI claiming patterns along with a simulation of the effect of the DRC increases on the present value of retired worker benefits. Sections 5 and 6 summarize our identification strategy and our empirical results, respectively, before we conclude in Section 7.

II. BACKGROUND

We first provide an overview on how an individual's monthly Social Security retired worker (as opposed to disabled worker, spousal, etc.) benefits are determined and how these benefits vary by claiming age. We highlight several factors that might influence an individual's claiming decisions, including the Delayed Retirement Credit (DRC), the Full Retirement Age (FRA), and the earnings test (ET). More details can be found in Appendix A. In the next section we document how we isolate the effect of the DRC, taking into account simultaneous changes in these other factors. Lastly, we discuss this paper in the context of the existing literature.

A. Social Security Claiming Rules

For those who qualify, the monthly OASDI retired worker benefit depends primarily on three factors. Firstly, the worker's average indexed monthly earnings (AIME), which is an average of the 35 highest years of indexed covered earnings,⁴ determines the monthly primary insurance

⁴ Only earnings that are subject to the OASDI payroll tax in each year count for the purposes of the AIME calculation. For example, in 2019, annual earnings above \$132,900 were not subject to this tax and thus maximum monthly earnings for the purposes of the AIME calculation would be \$11,075. Earnings in previous years are scaled up to account for increases in average economy-wide earnings over time. See: <https://www.ssa.gov/oact/cola/rtea.html>

amount (PIA). A second important factor is the age at which the worker claims benefits. An individual who claims benefits at the full retirement age (FRA) receives 100 percent of the PIA while one claiming before that age receives benefits scaled down by monthly early retirement reduction factors to account for the longer period of benefit receipt. In contrast, each month that a worker delays claiming beyond the FRA results in benefits being scaled up by the monthly delayed retirement credit (DRC). Finally, a retired worker's benefits may be reduced due to Social Security's earnings test. The earnings test has been present since the creation of the Social Security program in 1935, though it was eliminated for those receiving benefits at or beyond the FRA in April of 2000. For an individual claiming retired worker benefits before FRA, the earnings test leads to a 50% phase out of OASDI benefits as annual earnings increase beyond a threshold (\$18,960 in 2021).⁵

B. The 1983 Social Security Amendments

The 1983 Social Security Amendments, aimed at tackling program solvency, substantially reformed the Social Security program. Prior to this amendment, the DRC had stood at just 3.0% per year but this was gradually increased to 8.0% for those born in 1943 and later. This legislation also increased the full retirement age, though these changes were phased in even more gradually. The full retirement age was left unchanged for workers born in 1937 and earlier (thus anyone aged 46 and up) while it was set at 67 for those born in 1960 and later. This FRA increase from 65 to 67 was phased in using two-month increments. Along with these changes, the 1983 amendments gradually reduced the amount of benefits at the earliest possible age of claiming of 62 at each age through the FRA. Once the changes are fully phased in, the fraction of an individual's PIA that the

⁵ Benefits that are withheld due to the earnings test are returned to the individual in the form of increased benefits after an individual reaches the Full Retirement Age.

worker could receive when claiming at age 62 will be just 70 percent, versus 80 percent for those born in 1937 or earlier (and 75 percent for those born from 1943 through 1954).

Figure 1. Delayed Retirement Credit and Full Retirement Age by Birth Year

Notes: Illustrates the Delayed Retirement Credit (DRC) and Full Retirement Age by birth year.

Figure 1 illustrates the evolution of the DRC and FRA for birth cohorts from 1919 through 1962. As the figure shows, the DRC starts at 3%, and steadily rises by half a percentage point starting with the 1925 birth cohort every two years. By the 1943 birth cohort, the DRC has risen to 8%, and remains steady at 8% for all subsequent birth cohorts. However, the Full Retirement Age is also changing as well, starting at age 65 up through the 1937 birth cohort and rising in two-month increments to age 66 for the 1943 through 1954 birth cohorts. This increases again to age 67 in two-month increments so that it reaches age 67 by the 1960 birth cohort. Given that both the DRC and FRA are dependent on birth year, simultaneous shifts in the FRA might confound our estimates

for the effect of DRC changes, especially those occurring for the 1938 and later birth cohorts. We discuss this in much greater detail in our sample selection and empirical analysis sections below.

We also summarize the effects of the FRA and DRC changes for the 1919 through 1954 birth cohorts in Table 1, illustrating how the FRA and DRC affects the amount of benefits received. In the last two columns, the values are the fraction of the PIA the individual will obtain when claiming at age 62 or age 70. For example, for the 1919 birth cohort, claiming at age 70 would lead to receiving 115 percent of the PIA in monthly benefits, while for the 1937 birth cohort, claiming at that same age would produce 132.5 percent of the PIA in monthly benefits.

Table 1. Social Security Benefit Schedule

Birth Year	FRA	DRC (%)	% PIA Claiming at Age 62	% PIA Claiming at Age 70
1919-24	65	3.00	80.00	115.00
1925-26	65	3.50	80.00	117.50
1927-28	65	4.00	80.00	120.00
1929-30	65	4.50	80.00	122.50
1931-32	65	5.00	80.00	125.00
1933-34	65	5.50	80.00	127.50
1935-36	65	6.00	80.00	130.00
1937	65	6.50	80.00	132.50
1938	65, 2 mo.	6.50	79.17	131.42
1939	65, 4 mo.	7.00	78.33	132.67
1940	65, 6 mo.	7.00	77.50	131.50
1941	65, 8 mo.	7.50	76.67	132.50
1942	65, 10 mo.	7.50	75.83	131.25
1943-54	66	8.00	75.00	132.00
1955	66, 2 mo.	8.00	74.17	130.67
1956	66, 4 mo.	8.00	73.33	129.33
1957	66, 6 mo.	8.00	72.50	128.00
1958	66, 8 mo.	8.00	71.67	126.67
1959	66, 10 mo.	8.00	70.83	125.33
1960+	67	8.00	70.00	124.00

Notes: Full retirement age (FRA), annual Delayed Retirement Credit (DRC), and PIA benefit adjustment rate for selected claiming ages by birth year.

C. Related Literature

Our work builds on a body of previous literature that has investigated the determinants of claiming Social Security benefits. Previous studies have found that in terms of strictly financial calculations, there is a substantial benefit to delaying claiming (Coile et al. 2002; Sun and Webb 2009; Shoven and Slavov 2014b). For example, Shoven and Slavov (2014a) finds that at relatively low interest rates, similar to those that prevail today, primary earners with average life expectancy should delay benefits to age 70 to maximize the expected present value of benefits. Coile et al (2002) finds that while incentives to delay vary according to life expectancy or the marital status of the claimant, in most cases the gains from delaying are substantial. Yet very few individuals claim after FRA, even though people on average are claiming later than they did 30 years ago. (Purcell, 2020). Most of this previous research suggests that relatively little is known regarding the mechanisms through which people decide to claim earlier than what is predicted through economic theory.⁶ An investigation of the impact of the policy-induced increase in the delayed retirement credit therefore remains an important question to be answered.

However, considerably less work has focused on examining how policy levers can be used to influence claiming behavior and whether individuals' claiming margins are responsive to program incentives. A body of literature in both within and outside the United States consistently finds that individuals respond to increase in full retirement age by delaying claiming benefits, and/or delaying retirement (Desphande, Fadlon and Gray (2020); Manoli and Weber (2016); Lalive and Stabuli (2016); Behaghel and Blau (2012); Fehur, Kallweit and Kindermann (2012);

⁶ The previous empirical research on claiming patterns consistently finds that people typically claim significantly earlier than what economic theory suggests would be optimal (Goda et al. 2018; Shoven and Slavov 2014a; Shoven et al. 2017; Rohwedder and van Soest 2006; Mastrobuoni 2009). Numerous factors, such as financial literacy, mistrust in the program, liquidity constraints, mortality risk, undervaluing of annuitized income, social norms, and framing are studied. There is not a consensus among these and related studies regarding the influence of these factors, except for interest rates and mortality risk.

Mastrobuoni (2009); Borsch-Supan and Berkel (2003)). While changing the FRA is one policy lever, an underexplored and potentially important policy lever independent of the FRA is to increase benefits for postponing claiming.⁷ Our study on the changes to the DRC complements this literature and broaden our understanding of how individuals respond to different financial incentives.

The closest work to ours is Pingle (2006), which utilizes the changes in the DRC to explore the effects on men's employment, using the Survey on Income and Program Participation (SIPP) and finds substantial DRC-induced labor supply increases for men in the 65 to 69 age group. However, this paper does not explore the effect of the DRC changes on Social Security claiming decisions. Additionally, Benitez-Silva and Yin (2009) find suggestive evidence that increases in the DRC did not lead to substantial changes in claiming behavior. Beyond the United States, Gorry, Lee, and Slavov (2020) examine a policy change in United Kingdom that increased benefits for delaying claiming (akin to the DRC) and finds that the more generous benefits reduced the fraction of men receiving pensions at the earliest possible age.

The existing literature on the determinants of individual claiming decisions and the effect of the DRC has two main shortcomings. First, existing studies are often limited to using publicly available data sources. Consequently, it is difficult to precisely measure Social Security claiming behavior as well as other key factors, such as lifetime earnings, benefit amounts, and exact year of

⁷ Additionally, there might be policy reforms that change the financial incentives to delay retirement. In the U.S., changes in the earnings test affect retirement decisions (Gelber, Jones, Sacks, Song 2022). Ferrari (2017) finds that the 'super-bonus' reform in Italy in 2004 that provided financial incentives to postpone retirement resulted in 30% reduction in retirement probability. Saporta-Eksten, Shurtz, and Weisburd (2021) look at the effect of changes in the implicit tax to delay retirement on employment in Israel, estimating labor supply elasticities and how working affects longevity. This paper is complementary to this literature. While these existing papers carefully estimate individual responses to retirement incentives, our paper investigates a related, but distinct reform targeting claiming. Retirement need not coincide with claiming of benefits, though individuals who delay retiring might also claim benefits later. In addition to looking at claiming responses to DRC changes, we also investigate possible employment effects.

birth (given that year of birth determines benefit rules). Another challenge for many of the previous studies is the absence of a plausibly exogenous source of variation with which to reliably estimate causal effects. Since there is an exact relationship between the age at which people claim Social Security, the calendar year in which they claim, and the delayed retirement credit level (which is determined by their birth year), identification of the true effect of the change in DRC that takes into account both the effect of age and of calendar year is difficult.

The DRC is determined uniquely by birth year and claiming year, so disentangling calendar year and age effects is a challenge. Studies note this difficulty and treat policy changes that vary at the cohort level as plausibly exogenous shocks (Mastrobuoni 2006, Pingle 2006, Duggan et al 2007, Engelhardt et al 2020). While researchers take care to test the robustness of the ensuing results, it is difficult to rule out the possibility that people from different birth years are different in unobserved ways. For example, if researchers do not account for the time trend effect where people claim later due to increased life expectancy in general or due to changes in interest rates over time, they might erroneously conclude that an increase in DRC raises the likelihood of claiming beyond the full retirement age.

In this study, we leverage the rich administrative micro-data from the Social Security Administration to track an individual's lifetime earnings, date of claiming, Social Security claiming type, and demographics, including birth date. In addressing the inherent identification concerns, we utilize a regression discontinuity with a second difference (RD-DD) design to estimate the causal effect of the substantial increase in Social Security's delayed retirement credit. Using our data on claimant characteristics, we can investigate whether the reaction to the greater financial incentive to delay claiming is statistically meaningful, and whether the effects vary with claimant characteristics.

III. DATA & ANALYSIS SAMPLE

We use several sources of administrative data from the Social Security Administration to create the primary dataset for our empirical analyses. We begin with the 10 percent sample of the Master Beneficiary Record (MBR) extract, containing the history of OASDI receipt for the primary beneficiary and other beneficiaries (e.g. spouse or child dependents), and merge it with the corresponding Master Earnings File (MEF), which provides the annual taxable earnings data from 1951 through 2016, and with the Numident extract. The Numident is used as a source of demographic and death data for all individuals, including those who are unobserved in the MBR.

Table 2. Sample Restrictions

	Total	Male	Female
Sample is in NUMIDENT, MEF, and MBR file primary beneficiaries ¹	14,848,075	8,268,923	6,579,152
Remaining sample after exclusions:			
Keep those born in 1923-1933, inclusive	2,035,642	1,149,995	885,647
Exclude DI beneficiaries	1,692,399	917,362	775,037
Keep only those Fully insured at age 61 for OASI ²	1,548,571	881,904	666,667
Keep only those Alive at age 62	1,536,911	873,213	663,698
Keep only OASI retirement beneficiaries, i.e. exclude spouse/widow or all other beneficiaries	1,509,049	864,810	644,239
Exclude those with OASI claim prior to age 62	1,508,310	864,272	644,038
Restrict the sample to birth months 1-3 and 10-12 ³	679,496	388,999	290,497
Final Sample	679,496	388,999	290,497

¹ We start with this sample, for which we could match the records in NUMIDENT file, in the MEF (those with at least a year of positive earnings), and in MBR file (primary beneficiaries).

² To be fully insured for OASI, workers born in 1929+ must have at least 40 quarters of coverage or 10 years of work.

³ This is our regression analysis sample. Hence, for the 1923 birth cohort we also exclude those born in January-March, and for the 1933 cohort we exclude those born in October-December.

To create our main analysis sample, we make a series of sample restrictions to limit to individuals who are the primary claimants (beneficiaries) of Social Security retirement benefits (i.e., they claimed benefits on their own earning records) as documented in Table 2. We restrict to individuals who do not claim Social Security Disability Insurance (SSDI) benefits at any time,

those who are insured for OASI retired worker benefits (i.e., have at least 40 quarters of coverage or 10 year of work), and who are still alive at age 62 (the first possible age for claiming retired worker benefits). We also limit to those who claim at ages of 62 or above. Very few individuals claim retired worker benefits before age 62; we remove those who claim prior to age 62 since no individual is permitted to claim OASI before age 62 and therefore must be an error in the data.

The main outcome variable of interest in our analysis is whether an individual claims Social Security retirement benefits for the first time on or after one year beyond their full retirement age. An individual will start receiving DRC adjusted benefits when claiming at any month after the FRA, so those who claim between FRA and one year after FRA will also receive a monthly benefit that exceeds the PIA due to the delayed retirement credit. We focus on a full year (12 or more months) after the FRA to better ensure that we are capturing the effects of the DRC-induced later claiming and to limit measurement error that might arise for those who accidentally claim just a few months after FRA. Furthermore, it might not be widely known that DRC benefits are applied at the monthly level. Claiming at ages one year after FRA provides a natural starting point for plausibly attributing the claiming that we observe in the data as intentional later claiming. Our results are robust to an alternative measure, of claiming at ages 65 and 6 months or over. We also estimate how the DRC affects labor supply. We additionally include outcome variables of whether an individual has any labor earnings at ages before the FRA (ages 62 through 64) and whether the individual has any earnings at ages after the FRA (ages 66 through 69).

Our main analysis focuses on cohorts born between 1923 and 1933, which includes several birth cohorts with an annual DRC of 3.0 percent (1923 – 1924), up to cohort with a DRC of 5.5 percent (1933), and 8 birth cohorts with a DRC between 3.5 percent and 5.0 percent (1925 – 1932). These birth cohort restrictions do not fully encompass all DRC increases, since the DRC rises to

8.0 percent for the 1943 and subsequent birth cohorts. However, we restrict up to the 1933 birth cohort to produce a sample of individuals who do not also face concurrent changes in other Social Security claiming factors to isolate the effect of the DRC more reliably. Firstly, the Full Retirement Age (FRA) starts to increase beginning with the 1938 birth cohort. Behaghel and Blau (2012) have shown that individuals are highly responsive to the changes in the FRA, with claiming patterns for many moving in lockstep with FRA increases. Therefore, we remove birth cohorts born on or after 1938, and thus only consider cohorts that faced an unchanging FRA of exactly age 65 in our main analysis.

Secondly, we exclude birth years whose claiming is most affected by the removal of the earnings test in 2000 for those beyond FRA. On April 7th of 2000, Congress enacted the Senior Citizens' Freedom to Work Act of 2000, which removed the earnings test for those at or older than FRA (see Song and Manchester (2007) for a full discussion of the legislation and the predicted effects on labor supply). While an individual need not claim simultaneously with retirement, this change in the earnings test rules likely affected working decisions for these groups (Gelber et al. (2022) shows that the earnings test affected employment) and thus claiming behavior. Even if a person's work decisions were not affected, the individual may decide to claim earlier due to the post-FRA earnings test elimination. For example, an individual who previously worked well beyond age 65 may have decided to delay claiming social security benefits due to the earnings test. With this eliminated, the individual might now decide to claim earlier.

Figure 2. Fraction of Men Claiming 1 Year After FRA by Birth Year

Notes: The figure plots the share of individuals who claim Social Security after one year past their FRA for male claimants. The numbers are authors' calculations from the 10% MBR sample.

This partially explains why in Figure 2, we see that the fraction of men claiming retired worker benefits one year or more after FRA fell very sharply from 5.6% for the 1933 cohort to 1.5% for the 1935 cohort after steadily increasing for previous birth cohorts. This dramatic fall explains the phenomenon where workers who previously delayed claiming due to the presence of earnings test no longer saw the need to delay once it was removed in 2000. Table 3 shows the birth cohorts directly affected by the earnings test. Those born in 1930 turn 70 in 2000 when the change in earnings test is introduced, so the first row in Table 3 shows that their claiming behaviors are unaffected (denoted with a 0) from age 62 to 70. In contrast, those born in 1938 turn 62 in 2000, so the second to the last row in Table 3 shows that their claiming behaviors are affected (denoted

with 1) by the policy change for the entire duration between age 62 and age 70. Those born between 1931 and 1937, however, are affected for a subset of the duration, which makes it difficult to separate the effect of increase in DRC on claiming ages from change in behavior induced by introduction of the change in earnings test.

Table 3. Claiming Behavior Affected by Earnings Test

Birth Year	62	63	64	65	66	67	68	69
1930	0	0	0	0	0	0	0	0
1931	0	0	0	0	0	0	0	1
1932	0	0	0	0	0	0	1	1
1933	0	0	0	0	0	1	1	1
1934	0	0	0	0	1	1	1	1
1935	0	0	0	1	1	1	1	1
1936	0	0	1	1	1	1	1	1
1937	0	1	1	1	1	1	1	1
1938	1	1	1	1	1	1	1	1
1939	1	1	1	1	1	1	1	1

Note: This table indicates whether the claiming behavior at each age for each birth year could have been affected by the removal of the earnings test in 2000. For the claiming age and birth year affected by the removal of the earnings test, we assign 1. We assign 0 if otherwise. We exclude birth years greater than or equal to 1934 in the main sample due to the removal of earnings test.

To identify the share of those claiming after or at age 66, who are unaffected by the earnings test, we restrict the sample of birth years to those born on or before 1933. We note that while those born before April of 1934 are also arguably unaffected by the earnings test for this outcome variable, we exclude the birth year 1934 entirely since those born later in the year would be affected. The earnings test likely induced a change in behavior even for those born before April 1934, as seen by the steep decline initiating with the birth month of January 1934 in Figure 2.

Finally, we further restrict the sample to men, due to large changes in the working and claiming behavior of women over the study period (similar to Coile et al. (2002), Pingle (2006)).

We include results for women separately in the appendix. There are several reasons why we analyze results for women separately from those of men in this period. First, there are large compositional changes in the share of women who claim benefits as the primary claimant, compared to claiming as a spouse. Given that we are concerned with the behavior of the primary claimant, for women, we cannot rule out that changes in the DRC over time happen concurrently with the changes in the composition of those who decide to claim as the primary or spouse. In fact, the fraction of aged women who claim as the primary beneficiary decreased from 59.5 percent in the 1923 cohort to 51.2% in the 1933 cohort, offset by increases in those who claim as the spouse.⁸ Meanwhile, consistently around 97 percent of men claim as the primary beneficiary. Second, women in these birth years tend to have significantly lower lifetime earnings compared with men, and thus their decisions to claim might look very different from those of men's. For example, in the 1933 birth cohort, the 40th percentile AIME was \$2063 for men, while it was just \$719 for women. Given the age difference between spouses, along with the fact that couples tend to align the timing of their retirement, the DRC is likely to affect the claiming decisions for women differently. Table 2 illustrates changes in the number of observations as we apply all our above-mentioned selection criteria, leaving us with a sample of 388,999 men born from 1923 through 1933 who were alive on their 62nd birthday and not previously on SSDI.⁹

⁸ Based on authors' calculations. We tabulate share who claim as the primary for OASI benefits, out of the total number who claim as the primary for OASI, aged spouse, and aged widower benefits. This variable captures claim type by the type of initial entitlement, and are thus mutually exclusive categories. Some of the initial benefits could come from dual entitlement.

⁹ Note for our final regression sample, we additionally restrict to individuals born in months of October-December and January-March. Our regression methodology (discussed in Section V) relies on comparing individuals born right around the end of the calendar year, since DRC is determined by birth year. Restricting our sample in this manner allows us to compare those who are plausibly similar in nature with the exception of the DRC.

Table 4. Summary Statistics for Men

	Mean	St. Dev	Min	Max	N
Claim at 66+	0.046	0.209	0	1	388999
Birth Year	1928	2.902	1923	1933	388999
DRC Changes in Window	0.499	0.500	0	1	388999
Birth Month: Jan, Feb, Mar	0.506	0.500	0	1	388999
Black	0.077	0.266	0	1	388210
Other Race	0.025	0.157	0	1	388210
PIA	486.45	177.86	5.79	1677.47	388999

Note: Summary statistics for our main regression sample, derived from the 10% Social Security administrative data. Includes men in birth cohorts 1923-1933 for those born in months Jan-March and Oct-Dec. A Birth Window is a 6-month window around January of a calendar year (Oct-March). The PIA is the Primary Insurance Amount, derived from the age 62 AIME.

In Table 4, we tabulate summary statistics of the main variables for the regression sample, with corresponding statistics for women in Appendix Table A1. We have a total of 388,999 men in our sample who were born between 1923 and 1933. Approximately 700 individuals have missing information on race; some regression specifications utilize information on race and thus restrict to those without missing race information. Out of the 10 birth windows (e.g. 1923-24, 1924-25, etc.) between 1923 and 1933, where birth year changes from October of one year to March of the next year, there are five windows in which the DRC changes by 0.5 percentage points. In this regression sample, 4.6% of all people claim on or after the month in which they reach age 66. The average primary insurance amount (PIA) (adjusted to 2012 dollars using the GDP deflator) is \$486.45 for our sample.¹⁰ In the analysis, we use PIA decile dummies as controls. PIA is

¹⁰ While this amount may seem relatively low compared with the average 2019 monthly retired worker benefit of about \$1,500, it is worth remembering that the maximum earnings subject to social security taxes was quite low during the 1950s and 1960s. For example, in 1954 average annual earnings were \$3,156 while the maximum taxable earnings were just \$3,600. The corresponding numbers in 1965 were \$4,659 and \$4,800, respectively. Relatively high average earnings below what it would have been, had the ratio of average earnings to maximum taxable wage ratio been similar to that of recent years.

calculated at age 62 for every individual in the sample, such that working past 62 does not impact the decile variable.

IV. TRENDS IN CLAIMING PATTERNS

A. Historical Claiming Patterns

By far the most popular choices among retired workers are to claim benefits immediately at age 62, the earliest possible claiming age, or to claim at the FRA (age 65 for all individuals in our sample). In fact, across these 1923 through 1933 birth cohorts, 54.1 percent of men claim at age 62. Meanwhile, on average 15.1 percent of men claim at age 65. Figure A1 displays the fraction of male individuals in our sample who claim retired worker benefits at each age (in years and months), with one graph for each year-of-birth between 1924 and 1933, inclusive. The share claiming at each age sums to one for each birth year. It is evident from this figure that across all 10 birth cohorts displayed, claiming immediately at age 62 and at the FRA are the most common. In fact, in the earlier birth groups, more than 40 percent claimed benefits at exactly age 62 and 0 months. Despite this fraction slightly waning over time, claiming at 62 remains by far the most popular choice for all 10 cohorts, with this group receiving 80 percent of the PIA.

As Figure A1 shows, claiming after the FRA is overall uncommon compared to claiming at the earliest eligibility age or at the full retirement age. Figure 2 illustrates the total fraction who claim on or after one year (i.e. 12 or more months) after their FRA by birth year. This share does trend gradually upward from 4.6 percent to 5.5 percent for the 1923 to 1933 birth cohorts. However, this fraction plummets to just 1.4 percent for the 1935 birth cohort, presumably because of the 2000 elimination of the earnings test for Social Security recipients at or older than the full retirement age. Some older workers presumably delayed claiming their retired worker benefits prior to this policy change to avoid having their benefits decreased due to the earnings test. But

the elimination of that earnings test encouraged more workers to claim earlier. Therefore, this sharp change in claiming behavior further reiterates the need to make sample restrictions due to the introduction of the earnings test.

B. How Does DRC Affect Claiming?

We begin with simulations of the net present value of claiming Social Security retired worker benefits at different ages, to highlight two notions: (1) increases in the DRC makes claiming benefits after the FRA financially more attractive and (2) there is heterogeneity in claiming incentives, where those greater lifetime earnings have a stronger incentive to claim later. These simulations are similar in spirit to Coile et. al. (2002), Sun and Webb (2009), Shoven and Slavov (2014a), and Alleva (2016). We model the stream of Social Security benefits as an annuity, where an individual will receive constant interval installments for the rest of life. We calculate the expected present value of claiming at different ages, where the details of the calculations are presented in Appendix B.

Our main simulation results can be summarized in Figure 3, where the expected present value of claiming at different ages, in age 62 dollars, is graphed for each claiming age and select birth years. For simplicity the PIA is set for both birth years to \$1000 with a 3% real discount rate (Coile et al 2002). As shown in the left panel, the drastic drop off in EPV after the FRA for the 1923 birth cohort that flattens out for the 1933 group suggests that the increases in the DRC substantially raise the EPV for a person with average mortality rates of claiming at later ages and thus helps make claiming later more actuarially fair. Figure 3 also shows the EPV profiles for those with low mortality rate profiles and lower mortality is also associated with claiming later. Intuitively, for those with longer life expectancies, claiming later implies a larger monthly benefit for a longer period of time. This, in turn, further implies that we expect the effects of the DRC to

be larger for those with higher lifetime earnings, since earnings is correlated with longer life expectancies.¹¹ In summary, on the margin, increases in the delayed retirement credit are likely to induce later claiming by some individuals.

Figure 3. Expected Present Value of Claiming

Notes: The expected present value is the sum of Social Security benefit streams for claiming at different months. Average mortality profiles for each birth cohort were taken from the 2018 Trustees Report, while low mortality refers to a mortality profile with 64% of the death probabilities at each age for the average profile, derived from Bosely et al (2018). Benefits are discounted by the real discount rate and survival probability at each age, calendar year, and sex. The PIA is fixed at \$1000 and the real discount rate is 3%, annually. The DRC of the 1923 and 1933 birth cohorts are 3% and 5.5% respectively. Vertical lines delineate the full retirement age of 65.

¹¹ See Appendix IIB and corresponding Appendix Figure A2 for a simulation of EPV by AIME quintiles.

V. EMPIRICAL STRATEGY

We estimate the causal effects of the increase in the delayed retirement credit by using a regression discontinuity with a second difference (RD-DD) strategy. In the ideal experiment, the DRC would be randomly assigned, so that we can attribute observed claiming behavior to differences in the DRC. In the absence of the random assignment, we can compare individuals who are plausibly very similar in nature, except for having different DRC rates. For those who are born around January 1st of a year, individuals born at the end of the previous calendar year are likely similar in nature to those born in early January of the new calendar year. Since DRC is assigned by the birth year, we compare differences in claiming behavior between people born after January 1st of the year when DRC increased by 0.5 percentage points (“post” time period), and people born right before the January 1st cutoff who did not see a corresponding change in their DRC (“pre” time period). We assume that an individual’s birth year is not manipulated for the purposes of obtaining a particular DRC rate 65 years in the future, which seems reasonable given that the legislation causing the DRC changes was not passed until 1983, several decades after all the individuals in our sample were born.

To control for the possibility that claiming decisions are influenced by calendar month-of-birth, we add additional robustness to our empirical design by introducing placebo windows in which the DRC remained constant. Since DRC increased every two birth years, birth cohorts in the window that experienced DRC changes have two ‘placebo control’ windows with constant DRC before and after the change in DRC. To illustrate this, consider a birth window that includes those born in October, November, and December of 1926 and those born in January, February, and March of 1927, where the DRC increased from 3.5 percent for the 1926 birth cohort to 4.0 percent for 1927 birth cohort. A simple comparison of claiming patterns of those born in 1926 who

had a 3.5 percent DRC with that of those born in 1927 who had a 4.0 percent DRC might be biased, given that there may be a month effect where people’s likelihood of claiming in each month might differ across calendar months. Furthermore, individuals born in 1923-1933 would be making claiming decisions in the late 1980s to late 1990s, a period with both large economic changes and the passage of major tax legislations. For example, changes in the tax structure due to OBRA90 might have affected individual claiming behavior. To eliminate this month effect and control for potentially confounding factors, we compare the claiming patterns of people in the window where DRC changes (1926-1927), with the corresponding claiming patterns of people born in the birth windows where the DRC does not change (1925-1926 and 1927-1928). Therefore, the 1926-1927 birth window is the “treated” unit, while the adjacent birth windows are the “control” units.

Each birth window where the DRC increases by 0.5 percentage points and the surrounding birth windows where the DRC does not change is an individual experiment. We can pool together all 5 experiments that occur throughout our main sample. Our main sample includes birth years 1923-1933, where the DRC increases from 3.0 to 5.5 percent. We begin with focusing on a 6-month bandwidth around each January 1st cutoff, where each birth window runs from October-December, and January-March. We estimate the average difference in claiming behavior between those who are born soon after January 1 with those born shortly before January 1 in those six-month windows when the DRC changes compared to windows where the DRC does not change with the following specification:

$$Y_i = \alpha + \delta_w + \gamma_m + \beta \cdot \text{Change Window}_i \cdot \text{PostJan1}_i + X_i\theta + e_i \tag{1}$$

In this specification, Y_i is a claiming outcome of individual i , *Change Window* is a variable that is equal to 1 if an individual i was born in the window of six months around a January 1st where the DRC changes, *PostJan1* takes on the value of 1 if individual i was born after the Jan 1st cutoff

and zero otherwise. Therefore, β is our coefficient of interest, which captures the effect of experiencing a 0.5 percentage point higher DRC, compared to those born in comparable windows around January who did not experience changes in DRC. We also include fixed effects for each January window, δ_w , to account for the possibility that claiming patterns are changing over time due to macroeconomic conditions, social norms, or other factors. There are also a full set of six calendar month-of-birth fixed effects, γ_m . We also include a set of individual-level controls X_i , such as the individual's PIA decile and race. This specification pools together all 5 DRC changes in our sample, as well as pooling together all January windows where the DRC does not change as the effective control groups.

In the RD-DD framework, an alternative specification is to include a function of a running variable:

$$Y_i = \alpha + \delta_w + \gamma_m + \beta \cdot \text{Change Window}_i \cdot \text{PostJan1}_i + X_i \theta + \pi \text{DaysSinceJan1}_i + \tau \text{DaysSinceJan1}_i \cdot \text{PostJan1}_i + e_i \quad (2)$$

The running variable, *DaysSinceJan1*, is the difference between the individual's birthdate and January 1st of a birth window. We additionally allow for different slopes with respect to our running variable above and below the January 1st threshold. As we will discuss in the robustness checks, our main coefficient of interest, β , remains virtually unchanged when we include the additional *DaysSinceJan1* terms. Therefore, we prefer to use Equation (1) as our main base specification due to simplicity and ease of interpretation.

Our research design assumes that individual characteristics evolve smoothly around the January 1st threshold in birth windows where the DRC changes, compared with birth windows where the DRC does not change. While we include a set of individual level controls, X_i , we additionally perform balance tests of our covariates using our main regression specification (Equation 1) and the alternative specification (Equation 2). As shown in Appendix Table A2,

demographics such as fraction men, Black, and PIA decile do not vary discontinuously across January 1st in treatment windows compared to control birth windows.

Our main outcome variable of interest is an indicator variable for claiming at least one year after FRA (i.e. claiming on or after the month in which an individual reaches age 66). We test for the presence of adverse selection in claiming by extending our analysis to subsamples of individuals with different PIAs. As predicted in the simulations, those with higher PIAs (and thus, the lowest mortality rates), have stronger incentives to claim later. We explore heterogeneous DRC effects for those in the above median PIA, below median PIA, and top decile PIA. Lastly, we extend our main analysis to additional outcome variables of any earnings at ages 62-64 and any earnings at ages 66-69, to explore how changes in the DRC affects labor supply.

VI. EMPIRICAL RESULTS

A. Results

We present our main results from Equation (1), shown in Table 5. Columns (1) – (4) reflect the results using the full 1923 - 1933 birth cohorts for men, where the DRC increased from 3.0 percent to 5.5 percent, but the FRA remained constant at age 65. Furthermore, the 2000 earnings test change would not have affected the decision to claim one or more years after FRA for any individuals in our sample. The outcome variable is an indicator variable that equals one if the individual claims retired worker benefits in the month that the individual reaches age 66 or later and is otherwise equal to zero. Each column adds control variables so that the fourth specification includes calendar month fixed effects, window fixed effects, and individual-level control variables including race and ten indicator variables for each cohort-specific PIA decile.

Table 5. The Effect of Increase in Delayed Retirement Credit on Claiming Behavior of Men

Sample	Outcome: Claim at Age 66+						
	Full				Below Median PIA	Above Median PIA	Top PIA Decile
	(1)	(2)	(3)	(4)	(5)	(6)	(7)

*** p<0.01, ** p<0.05, * p<0.1

Note: Data derived from the 10% Social Security Administration data, with restrictions outlined in Table 2. Columns (1) - (3) include the full sample of men in the 1923-1933 birth years and subsequent columns restrict to samples as indicated. In columns (4)-(7) with the inclusion of race controls, the sample is limited to observations without missing race information. All regressions utilize a 6-month window around January, thus including only those born in October-December and January-March. Those born in months without a full DRC window are also removed; for example, we remove those born in 1923 January - March, since there are no corresponding Oct-Dec observations. Mean Dep. Var is the average fraction claiming at 66+ for those in windows where DRC changes, born in Oct-Dec for the relevant samples. Robust standard errors in parenthesis.

The estimated effect of the DRC increase in all four specifications is positive, suggesting that – as expected – men are more likely to delay claiming when there is a greater financial incentive to do so. The coefficient of interest is on the interaction term of “Change Window” and “Post Jan”, which is the effect of experiencing a 0.5 percentage point increase in the DRC, compared to birth windows in which the DRC remains the same. We note that this coefficient remains stable even with the inclusion of additional controls. Taking column (4) as the most conservative specification, we estimate that a 0.5 percentage point increase in the DRC increases claiming at age 66+ by 0.25 percentage points, and this is statistically significant at the 10% level.

Given that 4.6 percent of those born before January in windows where the DRC changes claim at age 66 or over, this represents a 5.46 percent increase from the mean.

As predicted in our simulations, those with higher PIAs might be more affected by increases in the DRC, since claiming later is more attractive for these individuals who will obtain a larger monthly benefit for a longer period (since they face lower mortality rate profiles). We also test whether we observe this form of adverse selection in the data. Columns (5) – (7) of Table 5 displays results of regression specifications where we restrict to the below median PIA, above median PIA, and top decile PIA, respectively. We find that DRC did not have a significant effect on claiming behavior for any of the PIA groups. While this result may look puzzling, we attribute the loss of statistical significance in the aggregate effect to the reduction in number of observations in each specification. Since the magnitudes of the effects are relatively small and close to zero, one needs more statistical power, and thus a greater number of observations to avoid making a type II error. In terms purely of magnitudes, we find suggestive evidence of adverse selection, as our point estimates indicate that a 0.5 percentage point increase in DRC increased the share of men claiming later for those in the top PIA decile increased by 0.69 percentage points.

Appendix Table A3 shows analogous results of the effects of DRC increases for the sample of women. As discussed in the sample selection section, the claiming decisions of women in this sample are likely confounded with large changes in the composition of women who are the primary claimant. Furthermore, the claiming decisions of women are likely linked to that of their spouses, given that women tend to have lower lifetime earnings. With these other factors in mind, we see that women are overall unresponsive to changes in the DRC. This is in line with the existing

literature, which also document how men and women are differentially responsive to financial incentives to delay claiming.¹²

Next, we explore the role of liquidity and credit constraints in claiming behavior. Shoven et al (2017) fielded a survey and found that the most common reason for claiming before the FRA was that individuals needed the money. To investigate whether these frictions drive responsiveness to the DRC, we split the sample of claimants by whether the individual had any earnings at age 61, the year before any possible Social Security retirement claiming. Individuals with earnings at age 61 are likely less liquidity constrained than individuals without any earnings at the same age. We choose presence of earnings at age 61, since earnings at any later age is likely endogenous to claiming behavior and age 61 earnings get at liquidity right before any possible claiming that might occur starting at age 62. In Table 6 column (1), we see no statistically significant effect of any DRC induced claiming changes; however, in column (2), a 0.5 pp increase in the DRC increases claiming at age 66+ by 0.32 pp, or 6.56% off the baseline mean. This suggests that the overall DRC induced increases are driven by those with age 61 earnings and that liquidity constraints play an important role in claiming behavior.

In summary, the 1983 Social Security amendments substantially increased the benefits of claiming later through changes in the Delayed Retirement Credit, and this study reveals that men are modestly responsive in their claiming decisions, with most pronounced effects among the highest earners and those less likely hampered by liquidity constraints. Given that changes in the DRC affects claiming behavior, the natural extension is to understand whether these changes also

¹² Borsch-Supan and Berkel (2003) finds that the pension reform in Germany in 2002 that increased actuarial adjustment rate from 3.6% to 6% a year induced men to delay claiming more so than did women. Gory, Lee and Slavov (2020) finds that fraction of women working increased more than that of men in response to more generous pension deferral rules in United Kingdom in 2005.

correspond to differences in employment behavior. We consider how increasing the financial incentive to delay claiming affected both employment prior to the FRA (ages 62-64) and employment after the FRA (age 66-69). How increases in the DRC affects employment is theoretically ambiguous. On one hand, increases in the DRC might induce individuals to work longer given that claiming Social Security benefits coincides with retirement for many individuals (thus increasing employment). However, DRC increases may also decrease employment. Some individuals may be targeting a certain amount of lifetime benefits and individuals need not simultaneously retire and claim benefits. Since the DRC increases raise the net present value of claiming at each age, individuals may stop working earlier to reach the same lifetime benefits.

Table 6. Earnings and The Effect of Increase in Delayed Retirement Credit, Men

Outcome	Claim Age 66+	Claim Age 66+	Any Age 62-64	Any Age 66-69

*** p<0.01, ** p<0.05, * p<0.1

Note: Data derived from the 10% Social Security Administration data, with restrictions outlined in Table 2. Dollar amounts deflated to 2012 dollars. Columns (1)-(2) restrict to the sample of men as indicated. All men are born in the 1923-1933 birth years without missing race information. All regressions utilize a 6-month window around January, thus including only those born in October- December and January-March. Those born in months without a full DRC window are also removed; for example, we remove those born in 1923 January - March, since there are no corresponding Oct-Dec observations. Mean Dep. Var is the average of the outcome variable for those in windows where DRC changes, born in Oct-Dec for the relevant samples. Robust standard errors in parenthesis.

Table 6 columns (3) – (4) estimates equation (1) for a set of earnings and employment related outcome variables. In column (3), we sum together all earnings across age 62-64 and the

outcome variable of interest is any earnings at ages 62-64. Column (4) shows the analogous outcome variable for age 66-69. In columns (3) and (4), we see precisely estimated zero effects; a 0.5 pp increase in the DRC does not change whether the individual has any earnings before or after the FRA. For example, in column (3), the 95% confidence interval includes $[-0.0046, 0.0048]$, which is less than a 1% change in either direction of the mean. Altogether, our results illustrate of a picture of no or very small changes in employment due to the changes in the DRC. This finding is perhaps unsurprising; given the overall modest changes to claiming behavior, it is unlikely that the DRC increases are large enough to affect labor supply.

B. Robustness

We perform several sets of robustness checks to verify our main findings. First, we re-estimate the specifications shown in Table 5 by varying the birth window bandwidth. Our baseline sample utilizes a 6-month birth window around January, but we could have chosen an alternative length; a shorter bandwidth helps ensure that individuals are more similar in nature but decreases sample size and power. In Appendix Table A4 columns (1)-(7), we show the analogue to Table 5 with a 4-month birth window bandwidth, incorporating those born in November-December and January-February. The point estimates are in line with the main results, and we again see suggestive evidence of more pronounced effects of the DRC for those with larger lifetime incomes. Appendix Table A6 widens the birth window to an 8-month bandwidth, including those born in September-December and January-April. Again, we see that the estimates are in line with our main results. In Appendix Table A7 and A9, we show the same for the sample of women.

Second, we test whether our estimates are robust to an alternative definition of “claiming later”. Our main outcome variable is an indicator for claiming benefits at age 66 or later.

Individuals may not know that the DRC applies at the monthly level, and it is difficult to identify whether individuals who claim a few months into age 65 purposefully did so for the DRC or because they intended to claim at 65. We can alternatively define “claiming later” as claiming at age 65 and 6 months or later. In Appendix Tables A4, A5, and A6, columns (8)-(14) (and Appendix Tables A7-A9 for the sample of women) show the coefficient estimates for this alternative outcome variable, while also varying birth window bandwidths. Throughout all these tables, we consistently see that our estimates are robust to this alternative outcome variable.

Lastly, as discussed in Section 5, we show estimates for an alternate RD-DD specification (Equation 2). Appendix Table A10 presents the results from this specification for the sample of men and women. Column (1) reproduces our main results for ease of comparison. Adding the running variable, *DaysSinceJan1* in column (2), and adding the running variable interacted with *PostJan1* in column (3) produce nearly identical coefficients. We see the same results for the sample of women. This helps motivate our main regression specification, Equation (1), since the inclusion of these additional terms do not change our results.

C. Discussion

This paper finds that increases in the DRC did induce changes in claiming behavior, with no effects on labor supply. Increases in the DRC came about through the 1983 Social Security Amendments, a set of reforms aimed at tackling the long-term solvency of the OASI trust fund. We perform a back-of-the-envelope calculation to estimate how the DRC increase from 3% to 5.5% affected OASI expenditures, with details found in Appendix C. We estimate an upper bound on government savings of 193 million dollars. The DRC saves money because for the average individual in these birth cohorts, a 5.5% DRC is not large enough to make claiming after age 66 actuarially fair compared to claiming at the full retirement age. However, we do find suggestive

evidence that those with the largest lifetime earnings (which is correlated with longer life expectancies) are more responsive to DRC increases, further reinforcing that our calculations are upper bounds on government savings.

While we observe that changes in the DRC do encourage some men to claim retirement benefits later, on the margin, the overall rates of claiming after the Full Retirement Age are still quite low – as shown in Figures 2 and A1, the most popular age to claim by far is immediately at age 62, with another spike at the Full Retirement Age, and claiming later is overall rare. Therefore, while the DRC does mildly promote later claiming, we note the overall low rates of claiming later and highlight other factors at play. We have already identified the important role of liquidity constraints. Furthermore, in the context of the simulations presented in this paper, claiming is a function of the real discount rate and individual’s expectations of their own health and life expectancies. High discounting of the future and beliefs regarding poorer health could be especially important. For example, Goda et al (2018) found that many who claim earlier have sufficient liquidity to delay, but that those who claim earlier have worse self-reported health.

We highlight that informational frictions could also be dampening the effects of DRC increases. Liebman and Luttmer (2012) conducted a survey in 2008 to those between the ages of 50 and 70 to understand knowledge of Social Security program rules and to test interventions. While respondents largely knew that later claiming produces larger monthly benefits, they found that individuals were “unaware that benefit increases from delaying claiming are higher between the full-benefit age (generally age 66 in our sample) and age 70 than between age 62 and the full retirement age” and that individuals perceived a benefit increase in claiming between the ages of 70 and 74, which is not the case. Therefore, knowledge regarding the DRC might be quite limited or at least incomplete and thus reduce responsiveness to this change in financial incentives.

VII. CONCLUSION

Social Security represents the most important source of income for most elderly Americans. A number of changes have been made to the program during the last several decades. Arguably the most important set of changes were included in the 1983 amendments to Social Security, which increased the payroll tax rate and the full retirement age while also increasing the DRC. While this last provision actually represented an *increase* in the amount of benefits by increasing the actuarial adjustment beyond FRA, policymakers hoped it would also improve Social Security's financial standing. The most plausible mechanism for such an improvement was to lead individuals to claim later than they otherwise would have and to work longer as a result. At the time of the Amendments, Social Security benefits would be decreased for those working beyond FRA who had already claimed benefits.

We show in this paper that men did change the timing of their claiming of retired worker benefits in response to the large increases in the DRC. We take care to disentangle the effect of the DRC increase from other policy changes that took effect during our study period, including the increase in the full retirement age and the elimination of the earnings test for those receiving Social Security at or beyond their FRA. While we do estimate government savings, we do find suggestive evidence that the most responsive individuals to the DRC appear to be those with the largest lifetime earnings and highest expected present value of Social Security benefits.

It is worth noting that over the last several years, there has been a substantial increase in the fraction claiming benefits beyond the FRA. For example, from 2009 through 2019, the fraction of male retired workers claiming one or more months after their full retirement age (66 for essentially all post-FRA claimants during this period) increased from 4.1 percent to 16.2 percent

after having remained relatively unchanged in the preceding several years.¹³ However, the DRC reached 8 percent for the 1943 and subsequent birth cohorts. Therefore, the DRC increases would essentially have been fully phased in for those 66+ and thus the DRC is unlikely to be the primary driving force for the 2009 to 2019 increase. A variety of other factors could have contributed to this increase in claiming later. The economic recovery following the Great Recession could have encouraged later claiming to the extent that individuals desired to work longer following lost income or take on jobs due to better employment prospects. In addition, life expectancy continued to rise. Lastly, it could also be the case that it takes time for individuals to learn about the DRC or adopt new norms in delaying claiming. Future research should explore the causes along with the consequences of this change given the importance of Social Security benefits to most elderly Americans.

APPENDIX

A. Additional Details on Social Security Benefits

To qualify for retired worker benefits, an individual must have a sufficient work history, which includes 40 or more credits (at least 10 years) of covered employment or earnings that are subject to Social Security taxes and must also be at least 62 years old. In 2021, for a credit to “count”, an individual must have earned at least \$1,470, and a person who earned \$5,880 during the year would earn 4 credits of coverage.¹⁴

Once an individual qualifies for Social Security benefits, the amount of monthly benefits depend on lifetime earnings. The AIME is converted into the primary insurance amount (PIA) using progressive replacement rates of 90, 32, and 15 percent (SSA, 2019). For example, in 2020, the first \$960 of AIME was replaced at a 90 percent rate while the next \$4,825 of AIME was replaced at a 32 percent rate, with any remaining monthly earnings in the AIME (beyond \$5,785) replaced at a 15 percent rate up to the taxable maximum.

There are three ways the benefit amount can change after claiming: a cost of living adjustment (COLA), additional work, or an adjustment at full retirement age if one had received reduced benefits and exceeded the earnings limit. COLA affects monthly benefits by adjusting benefits following the Department of Labor’s Consumer Price Index. In 2021, the announced adjustment was 1.3 percent, and affected more than 70 million beneficiaries. Additional work after receiving benefits could potentially increase the benefit amount if the additional earnings is higher than the highest thirty-five years of earnings before claiming. Lastly, a person who decided to take benefits early at a reduced rate while continuing to work may experience increases in benefits once

¹⁴ The amounts are of course lower in previous years: see <https://www.ssa.gov/oact/cola/QC.html>

they reach the full retirement age if they exceeded the allowable earnings limit and had some of the benefits withheld.

We next provide more background for the 1983 Social Security Amendments. In 1981, President Ronald Reagan created the National Commission on Social Security Reform, a bipartisan group created due to the inability of Congress and the President to agree on reforms aimed at addressing the financial problems of two trust funds: The Old-Age and Survivors Insurance and The Disability Insurance. At that time, the program had run annual deficits for several consecutive years and the program's trust fund had shrunk to just one-sixth of annual expenditures (versus approximately 2.7 times today). These deficits were occurring despite a substantial increase during this period in the maximum amount of each worker's earnings subject to OASDI taxes along with a corresponding increase in the program's tax rate.

The National Commission was tasked with identifying sources threatening the financial insolvency of the program and “analyze potential solutions to such problems that will assure the financial integrity of the Social Security System ... and provide appropriate recommendations” (Executive Order 12335). The recommendations of the National Commission made their way into the 1983 Social Security Amendments, including the increase in the FRA and in the DRC.

B. Social Security Claiming Simulations

B1. Calculating Expected Present Value

The decision to start benefits at age 62 (the earliest qualifying age) or at a later age is influenced by the fact that monthly benefits are adjusted by a rate schedule. Therefore, claiming at age 62 means that the retiree will start receiving benefits immediately, but the amount obtained each month will be less than, say, claiming at age 64, 66, or 68. However, waiting to age 68

presents other challenges: there are forgone benefits in the six years from age 62 through age 68, which implies the receipt of fewer years of benefits.¹⁵

In the simplest possible formulation to highlight the impact of the DRC and other key parameters, we assume that individuals behave as if they seek to maximize the following expected present value of their Social Security benefit streams of claiming at different months:

$$EPV_{m,b} = (PIA \cdot \delta_{m,b}) \sum_{t=m}^A [S_t(1+r)^{-t}] \tag{3}$$

In this equation, $m = 0,1, \dots,96$ is the number of months since age 62 that an individual can choose to claim benefits. PIA is the individual's primary insurance amount, and it is adjusted by the adjustment factor, $\delta_{m,b}$, which is dependent on the month of claiming and the birth year, b . This adjustment factor is either the early retirement factor for those who claim before the FRA, or the delayed retirement credit for claiming after the FRA. We abstract from the effects of the cost-of-living adjustment since it will be offset by inflation and thus the PIA (multiplied by the adjustment factor) remains constant for all of the remaining years. Then, we sum over the discounted cash flow of receiving the benefit at all future ages, at real discount rate r and up to the maximum age, A . However, we must also account for the probability of an individual being alive at each age, which is captured by the inner term, S_t . S_t is the probability of an individual surviving to month t conditional on being alive at age 62 and 0 months ($S_0 = 1$). For example, for the age 62 and 0

¹⁵ One need not simultaneously claim Social Security benefits and retire from working, but for many, these decisions occur at the same time. This simulation abstracts from this and assumes those who claim later do not work for longer. Adding the tradeoff of working longer would make the simulation richer in nature. However, for the purposes of making the model as simple and transparent as possible to illustrate the relationship between claiming age and DRC, we believe including the working longer margin would only introduce complexity and not allow us to highlight these key channels. Working longer likely affects the worker's AIME/ PIA and to the extent the earnings are subject to the earnings test, might in turn affect the DRC and actuarial adjustment factor, creating substantial complexity.

month perspective, the Social Security benefit the individual will receive at age 70 and 0 months is the monthly benefit, discounted by the probability of surviving to age 70, and the real interest rate over the 8 years (captured by the $(1 + r)^{-t}$ term). The survival rates are obtained from the SSA historical and projected death probabilities for men, derived from the 2018 Trustees Report. We allow survival rates to differ by year of birth. The PIA adjustment factor is detailed in table 2.A20 of the 2019 *Annual Statistical Supplement*.

B2. EPV Simulations by AIME Quintile

Income affects the EPV of Social Security benefits through two channels: (1) higher income translates into higher AIME and PIA, and (2) higher income individuals experience lower mortality rates. In this simulation, we fix the birth cohort at 1933 (where the FRA is 65 and the DRC is 5.5%) and the real discount rate at 3%, annually. Using our sample, we find the AIME quintile cutoffs by birth year for men, to illustrate the EPV of claiming at different ages by AIME quintile. Bosley et. al. (2018) produce mortality ratios for AIME quintiles, sex, year, and age, where the mortality ratio is the death rate (by single year of age) of a particular quintile divided by the death rate of the overall group.

We next describe in detail how we derived mortality estimates from Bosely et. al. (2018). In this paper, the authors relate lifetime earnings to mortality, identifying how mortality rates vary for those with different AIME. In Appendix A, Tables 4 through 8, the authors show the relative mortality ratios for retired worker beneficiaries, by sex and age group. The relative mortality ratio is the death rate of a particular AIME group relative to all individuals of that sex and age group. For example, in Table 4, men in the lowest AIME quintile and of age 62-64 in 1995 have 1.65 times the death rate of an average male in 1995 of age 62-64. Subsequent tables show these same results for different calendar years.

Ideally, we would like to have the mortality ratios by birth cohort, AIME quintile, and age. Unfortunately, these tables are not by birth cohort, but rather, calendar year. These tables track the 1995 through 2015 calendar years, for groups of ages up to age 84. Therefore, we chose the 1933 cohort such that we can track the mortality ratios for this cohort for different age groups across the different tables. We use the mortality ratios in the 1995 table for the 62-64 age group (since the 1933 birth cohort would be 62 in 1995), the 2000 table for ages 65-69 (the 1933 group would be 67 in 2000), and so on. Given that the tables only track ages up to 84, the 80-84 mortality ratios are used for all ages 80+. The final adjusted death probabilities are the product of the probability of death at a particular age and the mortality ratio for that age. For example, the quintile adjusted probability of death for a 63 year old born in 1933 is the death probability in 1996 for a 63 year old (derived from the 2018 Trustees Report) multiplied by the ratios in the 1995 table for the 62-64 age group.

As shown in Appendix Figure A2, the overall pattern is that higher AIMEs have significantly lower death probabilities, but this difference decreases for older ages. In comparing the lowest and highest quintiles, we can see that claiming later is more attractive for those with higher AIMEs, driven by the differential mortality ratios. We also note the fact that those with higher incomes are more likely to claim later. If this group also responds more to DRC increases, this may reflect a form of adverse selection - to the extent that those with higher incomes claim later further depleting Social Security trust funds, such an empirical finding might actually have negative consequences for the program's solvency.

C. Calculation of Back-of-the-Envelope Fiscal Effects

In order to estimate how DRC increases affected OASI trust fund expenditures, we calculate a “back-of-the-envelope” approximation with the following assumptions:

1) We assume that the marginal men induced by DRC to claim later would have claimed at age 65 absent the DRC changes. It is unlikely, for example, that the DRC would have changed the behavior of an individual who would have otherwise claimed at age 62.

2) Our main outcome variable of interest in paper is delaying claiming or claiming at age 66+. For birth cohorts 1923-1933, conditional on claiming at age 66+, the average claiming age is age 67. Combined with (2), we assume that on average, DRC induces individuals to claim at age 67 instead of age 65.

3) We assume no employment effects. This is in line with Table 6 of our main paper.

First, we estimate the amount of money OASI pays out for each marginal individual who responds to the DRC, should the individual claim at age 67 compared to claiming at 65. The amount of money paid by OASI for an individual claiming at a certain age can be thought of in terms of the expected present value (EPV) of claiming at that age. We take an individual born in 1923 (the earliest birth cohort we study) with the average mortality profile, a 3% real discount rate, and average PIA (\$486.45 in 2012 dollars, following Table 4). While this birth cohort has DRC of 3%, we simulate the EPV if the DRC were 5.5%, using the EPV equation (3) shown in Appendix Section B1:

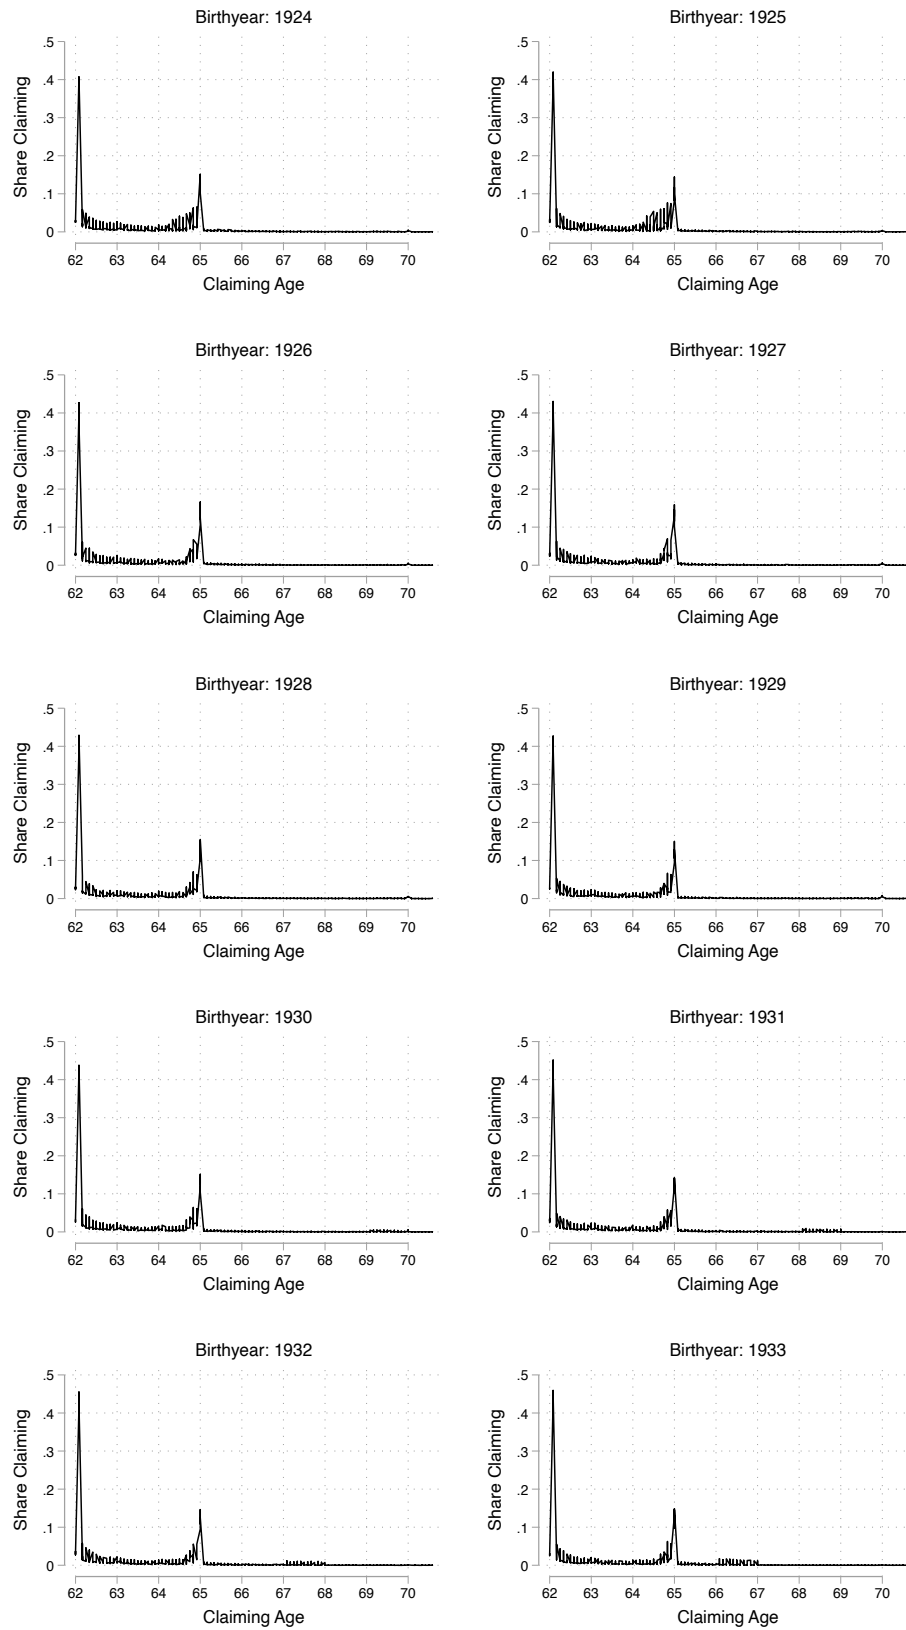

$EPV(\text{birth year} = 1923, \text{DRC} = 5.5\%, \text{claimage} = 67) - EPV(\text{birth year} = 1923, \text{DRC} = 5.5\%, \text{claimage} = 65) = -3960.$

Our paper estimates that a 0.5pp increase in the DRC increases claiming later by 0.25pp. Across the birth cohorts we study, the DRC increases from 3% to 5.5%, so the total increase in claiming later is $0.25 * 5 = 1.25\text{pp}$.

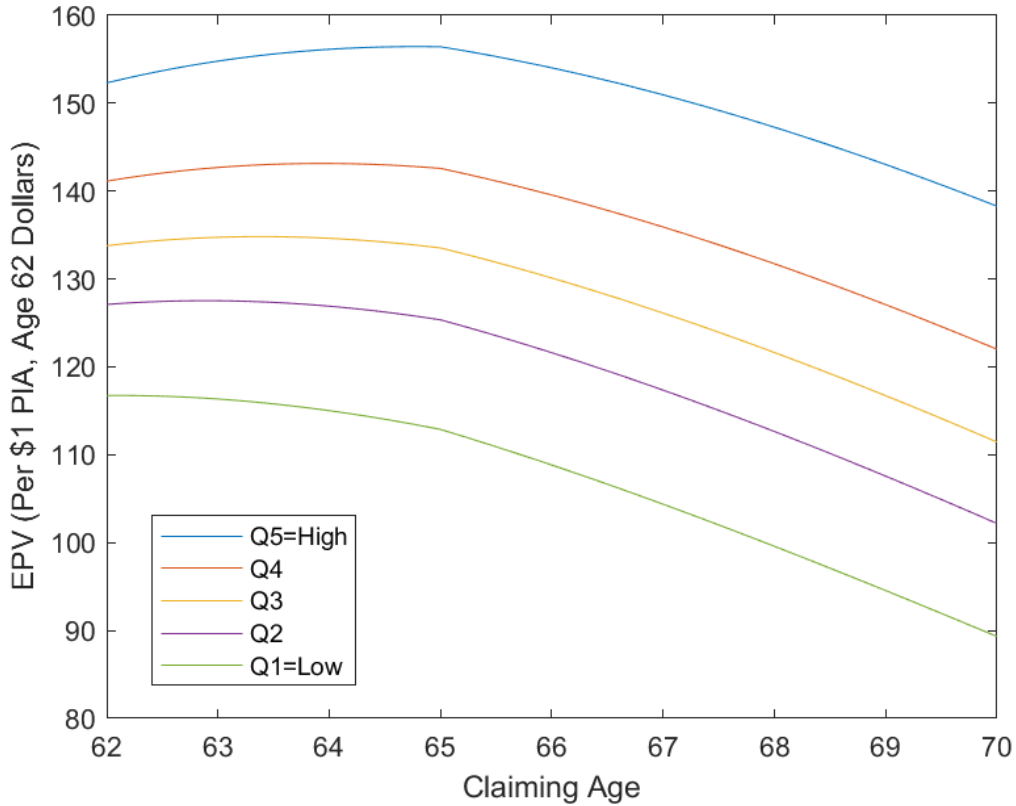

Across the 11 birth years, we have 388,999 men in our sample (Table 4). Since this is a 10% sample, we take that the total population would be 3,889,990 men.

Therefore, the back-of-the-envelope OASI change in spending due to the DRC increase from 3% to 5.5% is $-3690 * 0.0125 * 3,899,990 = -\193 million.

Appendix Figure A1. Social Security Claiming Patterns for Men

Appendix Figure A2. Expected Present Value (EPV) for AIME Quintiles

Notes: Simulations illustrate the expected present value by claiming age and AIME quintile. The EPV is the sum of Social Security benefit streams for claiming at different months. Average mortality profiles were taken from the 2018 Trustees Report, while mortality ratio by AIME quintile is constructed from Bosley et. al. (2018). Benefits are discounted by the real discount rate and survival probability at each age and calendar year. All simulations use birth year 1933, and real discount rate of 3%. PIA for each AIME quintile is derived from the average AIME of each AIME quintile cutoff.

Appendix Figure A3. Graphical Illustrations of the Main Regression Specification

A. Windows w/o DRC change

B. Window w/ DRC change

Notes: The figures plot linear fit of claiming behavior before and after cutoff on January 1st for the 1923-1923 birth cohorts. Panel A pools the windows of birthyears where individuals did not experience a change in DRC. Panel B pools together birth windows that experienced a 0.5 pp DRC increase.

Appendix Table A1. Summary Statistics, Women

	Mean	Stdev	Min	Max	N
Claim at 66+	0.062	0.242	0	1	290497
Birth Year	1928	2.917	1923	1933	290497
DRC Changes in Window	0.500	0.500	0	1	290497
Birth Month: Jan, Feb, Mar	0.508	0.500	0	1	290497
Black	0.090	0.286	0	1	289835
Other Race	0.023	0.150	0	1	289835
PIA	301.964	152.521	10.613	1730.717	290497

Note: Summary statistics for our main regression sample, derived from the 10% Social Security administrative data. Includes women in birth cohorts 1923-1933 for those born in months Jan-March and Oct-Dec. A Birth Window is a 6-month window around January of a calendar year (Oct-March). The PIA is the Primary Insurance Amount, derived from the age 62 AIME.

Note: Data derived from the 10% Social Security Administration data, with restrictions outlined in Table 2. All columns include the full sample of men and women in the 1923-1933 birth years, with the exception of columns (3)-(6), which includes only observations without missing race information. The outcome variable for each regression is labelled on top; these include indicators for Male, Black, or Other Race, and the PIA decile number (1-10). Odd numbered columns are estimates using Equation (1), whereas even columns are results using Equation (2). All regressions utilize a 6-month window around January, thus including only those born in October- December and January-March. Those born in months without a full DRC window are also removed; for example, we remove those born in 1923 January - March, since there are no corresponding Oct-Dec observations. Robust standard errors in parenthesis.

Note: Data derived from the 10% Social Security Administration data, with restrictions outlined in Table 2. Columns (1) - (3) and (8)-(10) include the full sample of women in the 1923-1933 birth years and subsequent columns restrict to samples as indicated. In columns (4)-(9) and (11)-(14) with the inclusion of race controls, the sample is limited to observations without missing race information. All regressions utilize a 6 month window around January, thus including only those born in October-December and January-March. Those born in months without a full DRC window are also removed; for example, we remove those born in 1923 January - March, since there are no corresponding Oct-Dec observations. Mean Dep. Var is the average fraction claiming at 66+ or claiming at 65 and 6m+ for those in windows where DRC changes, born in Oct-Dec for the relevant samples. Robust standard errors in parenthesis.
